Abstract

This paper combines the use of high order finite element methods with parallel preconditioners of domain decomposition type for solving electromagnetic problems arising from brain microwave imaging. The numerical algorithms involved in such complex imaging systems are computationally expensive since they require solving the direct problem of Maxwell’s equations several times. Moreover, wave propagation problems in the high frequency regime are challenging because a sufficiently high number of unknowns is required to accurately represent the solution. In order to use these algorithms in practice for brain stroke diagnosis, running time should be reasonable. The method presented in this paper, coupling high order finite elements and parallel preconditioners, makes it possible to reduce the overall computational cost and simulation time while maintaining accuracy.

Keywords: Schwarz preconditioners; high order finite elements; edge elements; time-harmonic Maxwell’s equations; microwave imaging.

1 Introduction

The context of this work is the solution of an inverse problem associated with the time-harmonic Maxwell’s equations, with the aim of estimating the dielectric properties of the brain tissues of a patient affected by a brain stroke. Strokes can be cast in two major categories, ischemic (80% of strokes) and hemorrhagic (20% of strokes), which result in opposite variations of these dielectric properties. In the following, we briefly describe this particular medical context as well as the application motivating the numerical model.

During an ischemic stroke the blood supply to a part of the brain is interrupted by the formation of a blood clot inside a vessel, while a hemorrhagic stroke occurs when a blood vessel bursts inside the brain. It is essential to determine the type of stroke in the shortest possible time in order to start the correct treatment, which is opposite in the two situations: in the first case the blood flow should be restored, while in the second one we need to lower the blood pressure. Note that it is vital to make a clear distinction between the two types of stroke before treating the patient: the treatment that suits an ischemic stroke would be fatal if applied to a hemorrhagic stroke and vice versa. Moreover, it is desirable to be able to monitor continuously the effect of the treatment on the evolution of the stroke during the hospitalization.

Usually stroke diagnosis relies mainly on two types of imaging techniques: MRI (magnetic resonance imaging) or CT scan (computerized tomography scan). These are very precise techniques, especially the MRI with a spatial resolution of 1 mm. However, a MRI machine

Figure 1: Imaging chamber of EMTensor (Courtesy of EMTensor GmbH).

is too big to be carried in ambulance vehicles and it is too expensive; a CT scan, which consists in measuring the absorption of X-rays by the brain, is harmful and cannot be used to monitor continuously the patient in hospital.

A novel competitive technique with these traditional imaging modalities is microwave tomography. With microwave imaging in a range of frequencies between 100 MHz and several GHz, the tissues are well differentiated and they can be imaged on the basis of their dielectric properties. The electromagnetic emissions are lower than the ones from mobile phones and the spatial resolution is good (5–7 mm). The first works on microwave imaging date back to 1989 when Lin and Clarke tested experimentally the detection of cerebral edema (excessive accumulation of water in the brain) using a frequency signal of 2.4 GHz in a head phantom. Other works followed, but almost always on phantoms or synthetic simplified models [1]. Despite these encouraging results, there is still no microwave device for medical diagnosis. The techniques designed by the University of Chalmers (Gothenburg, Sweden) [2] and by EMTensor GmbH (Vienna, Austria) [3] rely on technologies and softwares developed only in recent years. In both cases the improvement in terms of reliability, price and miniaturization of electromagnetic sensors is a key factor. In this approach, it is necessary to transfer the data to a remote HPC machine. The rapid telephony standards such as 4G and 5G allow to send the acquired measurements of the patient’s brain to a supercomputer that will compute the 3D images. Then these images can be quickly transmitted from the computer to the hospital by ADSL or fiber network.

Figure 1 shows the initial microwave imaging system prototype of EMTensor: it is composed of 5 rings of 32 ceramic-loaded rectangular waveguides around a metallic cylindrical chamber of diameter 28.5 cm and total height 28 cm, into which the patient head is inserted. Each of the 160 antennas alternately transmits a signal at a fixed frequency, typically 1 GHz. The electromagnetic wave propagates inside the chamber and in the object to be imaged according to its electromagnetic properties. The retrieved data then consist in the reflection and transmission coefficients measured by the 160 receiving antennas, which are used as input for the inverse problem. Since the inversion loop requires to solve repeatedly the *direct* problem of the time-harmonic Maxwell’s equations in high frequency regime, an accurate and fast solver of the direct problem is needed. In this paper accuracy is provided by a high order edge finite element discretization, and the resulting linear system is solved efficiently with the iterative method GMRES preconditioned with a parallel preconditioner based on domain decomposition methods.

The paper is organized as follows. In Section 2 the mathematical model of time-harmonic Maxwell’s equations in curl-curl form is presented, together with the associated boundary value problem to solve. In Section 3 the discretization method using high order edge finite elements is briefly described and in Section 4 the parallel preconditioner based on domain decomposition is introduced. Section 5 contains in the first part a comparison with exper-

imental measurements; in the second part we assess the efficiency of high order edge finite elements compared to the standard lowest order edge elements in terms of accuracy and computing time.

2 Mathematical model

To work in the frequency domain, we assume that the electric field $\mathcal{E}(\mathbf{x}, t) = \text{Re}(\mathbf{E}(\mathbf{x})e^{i\omega t})$ has harmonic dependence on time of angular frequency ω , where \mathbf{E} is its complex amplitude depending only on the space variable \mathbf{x} . Thus, considering a non magnetic medium with magnetic permeability μ equal to the free space magnetic permeability μ_0 , we can get the following second order time-harmonic Maxwell's equation:

$$\nabla \times (\nabla \times \mathbf{E}) - \gamma^2 \mathbf{E} = \mathbf{0}, \quad \gamma = \omega \sqrt{\mu \varepsilon_\sigma}, \quad \varepsilon_\sigma = \varepsilon - i \frac{\sigma}{\omega}. \quad (1)$$

Here ε_σ is the complex valued electric permittivity, related to the dissipation-free electric permittivity ε and to the electrical conductivity σ of the medium. Notice that if $\sigma = 0$, we have $\gamma = \tilde{\omega}$, $\tilde{\omega} = \omega \sqrt{\mu \varepsilon}$ being the wavenumber. Equation (1) is solved in the computational domain $\Omega \subset \mathbb{R}^3$ shown in Figure 1 (right): since alternately each waveguide $j = 1, \dots, 160$ transmits a signal, we denote by \mathbf{E}^j the solution of the corresponding boundary value problem, which differs only in the boundary conditions on the waveguides ports. Indeed, for each $j = 1, \dots, 160$, we solve the equation

$$\nabla \times (\nabla \times \mathbf{E}^j) - \gamma^2 \mathbf{E}^j = \mathbf{0}, \quad (2)$$

with metallic boundary conditions

$$\mathbf{E}^j \times \mathbf{n} = \mathbf{0} \text{ on } \Gamma_w, \quad (3)$$

on the cylinder and waveguides walls Γ_w , and with impedance boundary conditions on the port Γ_j of the j -th waveguide, which transmits the signal, and on the ports Γ_i of the receiving waveguides, $i = 1, \dots, 160, i \neq j$:

$$(\nabla \times \mathbf{E}^j) \times \mathbf{n} + i\beta \mathbf{n} \times (\mathbf{E}^j \times \mathbf{n}) = \mathbf{g}^j \text{ on } \Gamma_j, \quad (4)$$

$$(\nabla \times \mathbf{E}^j) \times \mathbf{n} + i\beta \mathbf{n} \times (\mathbf{E}^j \times \mathbf{n}) = \mathbf{0} \text{ on } \Gamma_i, i \neq j. \quad (5)$$

Here \mathbf{n} is the unit outward normal to $\partial\Omega$ and $\beta \in \mathbb{R}_{>0}$ is the propagation wavenumber along the waveguides. Equation (4) imposes an incident wave which corresponds to the excitation of the TE₁₀ fundamental mode \mathbf{E}_0^j of the j -th waveguide, with $\mathbf{g}^j = (\nabla \times \mathbf{E}_0^j) \times \mathbf{n} + i\beta \mathbf{n} \times (\mathbf{E}_0^j \times \mathbf{n})$. Equation (5) is an absorbing boundary condition of Silver-Müller giving a first order approximation of a transparent boundary condition on the outer port of the receiving waveguides $i = 1, \dots, 160$, with $i \neq j$. The bottom of the chamber is considered metallic, and we impose an impedance boundary condition on the top of the chamber.

The variational formulation corresponding to equation (2) together with boundary conditions (3), (4), (5) is: find $\mathbf{E}^j \in V$ such that

$$\int_{\Omega} [(\nabla \times \mathbf{E}^j) \cdot (\nabla \times \mathbf{v}) - \gamma^2 \mathbf{E}^j \cdot \mathbf{v}] + \int_{\bigcup_{i=1}^{160} \Gamma_i} i\beta (\mathbf{E}^j \times \mathbf{n}) \cdot (\mathbf{v} \times \mathbf{n}) = \int_{\Gamma_j} \mathbf{g}^j \cdot \mathbf{v} \quad \forall \mathbf{v} \in V,$$

with $V = \{\mathbf{v} \in H(\text{curl}, \Omega), \mathbf{v} \times \mathbf{n} = \mathbf{0} \text{ on } \Gamma_w\}$, where $H(\text{curl}, \Omega)$ is the space of square integrable functions whose curl is also square integrable. After discretizing these variational problems with the finite element method, we obtain 160 linear systems, one for each transmitting waveguide j and differing only in the right-hand side.

3 High order edge finite elements

To write a finite element discretization of the variational problem we introduce a tetrahedral mesh \mathcal{T}_h of the domain Ω and a finite dimensional subspace $V_h \subset H(\text{curl}, \Omega)$. The simplest

possible conformal discretization for the space $H(\text{curl}, \Omega)$ is given by the low order *Nédélec edge finite elements* (of polynomial degree $r = 1$) [4]: for a tetrahedron $T \in \mathcal{T}_h$, the local basis functions are associated with the oriented edges $e = \{n_i, n_j\}$ of T as follows

$$\mathbf{w}^e = \lambda_{n_i} \nabla \lambda_{n_j} - \lambda_{n_j} \nabla \lambda_{n_i},$$

where the λ_{n_ℓ} are the barycentric coordinates of a point with respect to the node n_ℓ . It can be shown that edge finite elements guarantee the continuity of the tangential component across faces shared by adjacent tetrahedra, they thus fit the continuity properties of the electric field.

The finite element discretization is obtained by writing the discretized field over each tetrahedron T as $\mathbf{E}_h = \sum_{e \in T} c_e \mathbf{w}^e$, a linear combination with coefficients c_e of the basis functions associated with the edges e of T , and the coefficients c_e will be the unknowns of the resulting linear system. For edge finite elements of degree 1 these coefficients can be interpreted as the *circulations* of \mathbf{E}_h along the edges of the tetrahedra:

$$c_e = \frac{1}{|e|} \int_e \mathbf{E}_h \cdot \mathbf{t}_e,$$

where \mathbf{t}_e is the tangent vector to the edge e of length $|e|$. This is a consequence of the fact that the basis functions are in duality with the degrees of freedom given by the circulations, that is:

$$\frac{1}{|e|} \int_e \mathbf{w}^{e'} \cdot \mathbf{t}_e = \begin{cases} 1 & \text{if } e = e', \\ 0 & \text{if } e \neq e'. \end{cases}$$

In order to have a higher numerical accuracy with the same total number of unknowns, we consider a *high order* edge element discretization, choosing the high order extension of Nédélec elements presented in [5] and [6]. The definition of the basis functions is rather simple since it only involves the barycentric coordinates of the tetrahedron. Given a multi-index $\mathbf{k} = (k_1, k_2, k_3, k_4)$ of weight $k = k_1 + k_2 + k_3 + k_4$ (where the $k_i, i = 1, 2, 3, 4$, are non negative integers), we denote by $\lambda^{\mathbf{k}}$ the product $\lambda_{n_1}^{k_1} \lambda_{n_2}^{k_2} \lambda_{n_3}^{k_3} \lambda_{n_4}^{k_4}$. The local generators of polynomial degree $r = k + 1$ ($k \geq 0$) over the tetrahedron T are defined as

$$\mathbf{w}^{\{\mathbf{k}, e\}} = \lambda^{\mathbf{k}} \mathbf{w}^e,$$

for all edges e of the tetrahedron T , and for all multi-indices \mathbf{k} of weight k . Note that these high order elements still yield a conformal discretization of $H(\text{curl}, \Omega)$: indeed, they are products between the degree 1 Nédélec elements \mathbf{w}^e , which are curl-conforming, and the continuous functions $\lambda^{\mathbf{k}}$. However, some of these high order generators ($r > 1$) are linearly dependent: the selection of a linearly independent subset to constitute an actual basis is described in [7], which provides further details about the implementation of these finite elements. Moreover, the duality property, which is practical for the implementation, is not satisfied for high order generators, but it can be easily restored as explained in [8].

Duality is needed for instance in FreeFem++, an open source domain specific language (DSL) specialized for solving boundary value problems by using variational discretizations (finite elements, discontinuous Galerkin, hybrid methods, ...) [9]. Several finite element spaces are available in FreeFem++, and the user can also add new finite elements, provided that the duality property is satisfied. For instance we implemented the edge elements in 3d of degree 2 and 3, which can be used by loading the plugin "Element_Mixte3d" and declaring the finite element space `fespace` using the keywords `Edge13d`, `Edge23d` respectively (the standard edge elements of degree 1 were already present in FreeFem++ and they are called `Edge03d`).

4 Domain decomposition preconditioning

The discretization of the problem presented in Section 2 using the high order edge finite elements described in Section 3 produces a linear system $\mathbf{A}\mathbf{u}^j = \mathbf{b}^j$ for each transmitting

Figure 2: The decomposition of the computational domain into 128 subdomains.

antenna j . Direct solvers are not suited for such large linear systems arising from complex three dimensional models because of their high memory cost. On the other hand, matrices resulting from high order discretizations are ill conditioned as shown numerically in [5] for similar problems, and preconditioning becomes necessary when using iterative solvers.

Domain decomposition preconditioners are naturally suited to parallel computing and make it possible to deal with smaller subproblems [10]. The domain decomposition preconditioner we employ is called *Optimized Restricted Additive Schwarz* (ORAS):

$$M_{\text{ORAS}}^{-1} = \sum_{s=1}^{N_{\text{sub}}} R_s^T D_s A_s^{-1} R_s,$$

where N_{sub} is the number of overlapping subdomains Ω_s into which the domain Ω is decomposed (see Figure 2). Here, the matrices A_s are the local matrices of the *subproblems* with impedance boundary conditions $(\nabla \times \mathbf{E}) \times \mathbf{n} + i\tilde{\omega} \mathbf{n} \times (\mathbf{E} \times \mathbf{n})$ as transmission conditions at the interfaces between subdomains. This preconditioner is an extension of the restricted additive Schwarz method proposed by Cai and Sarkis [11], but with more efficient transmission conditions between subdomains than Dirichlet conditions (see for example [12]).

In order to describe the matrices R_s, D_s , let \mathcal{N} be an ordered set of the unknowns of the whole domain and let $\mathcal{N} = \bigcup_{s=1}^{N_{\text{sub}}} \mathcal{N}_s$ be its decomposition into the (non disjoint) ordered subsets corresponding to the different (overlapping) subdomains Ω_s . The matrix R_s is the restriction matrix from Ω to the subdomain Ω_s : it is a $\#\mathcal{N}_s \times \#\mathcal{N}$ Boolean matrix and its (i, j) entry is equal to 1 if the i -th unknown in \mathcal{N}_s is the j -th one in \mathcal{N} . Notice that R_s^T is then the extension matrix from the subdomain Ω_s to Ω . The matrix D_s is a $\#\mathcal{N}_s \times \#\mathcal{N}_s$ diagonal matrix that gives a discrete partition of unity, i.e. $\sum_{s=1}^{N_{\text{sub}}} R_s^T D_s R_s = I$; in particular the matrices D_s deal with the unknowns that belong to the overlap between subdomains.

The preconditioner without the partition of unity matrices D_s , $M_{\text{OAS}}^{-1} = \sum_{s=1}^{N_{\text{sub}}} R_s^T A_s^{-1} R_s$, which is called *Optimized Additive Schwarz* (OAS), would be symmetric for symmetric problems, but in practice it gives a slower convergence with respect to M_{ORAS}^{-1} , as shown for instance in [7].

These domain decomposition preconditioners are implemented in the library HPDDM [13], an open source high-performance unified framework for domain decomposition methods. HPDDM can be interfaced with various programming languages and open source finite element libraries such as FreeFem++, which we use in the simulations.

5 Numerical results

In this section, all linear systems resulting from the edge finite elements discretizations are solved by GMRES preconditioned with the ORAS preconditioner as implemented in HPDDM. Each linear system to solve has several right-hand sides (one per transmitter),

and we use a pseudo-block method implemented inside GMRES which consists in fusing the multiple arithmetic operations corresponding to each right-hand side (matrix-vector products, dot products) in order to achieve higher arithmetic intensity.

All the simulations are performed in FreeFem++ interfaced with HPDDM. Results were obtained on the Curie supercomputer (GENCI-CEA).

In the following subsections, we first validate our numerical modeling of the imaging chamber by comparing the results of the simulation with experimental measurements obtained by EMTensor. Then, we illustrate the efficiency of the high order finite elements presented in Section 3 over the classical lowest order ones in terms of running time and accuracy.

5.1 Comparison with experimental measurements

The physical quantity that can be acquired by the measurement system of the imaging chamber shown in Figure 1 is the scattering matrix (S matrix), which gathers the complex *reflection and transmission coefficients* measured by the 160 receiving antennas for a signal transmitted by one of these 160 antennas successively. A set of measurements then consists in a complex matrix of size 160×160 . In order to compute the numerical counterparts of these reflection and transmission coefficients, we use the following formula, which is appropriate in the case of open-ended waveguides:

$$S_{ij} = \frac{\int_{\Gamma_i} \overline{\mathbf{E}^j} \cdot \mathbf{E}_0^i}{\int_{\Gamma_i} |\mathbf{E}_0^i|^2}, \quad i, j = 1, \dots, 160, \quad (6)$$

where \mathbf{E}^j is the solution of the problem where the j -th waveguide transmits the signal, and \mathbf{E}_0^i is the TE_{10} fundamental mode of the i -th receiving waveguide ($\overline{\mathbf{E}^j}$ denotes the complex conjugate of \mathbf{E}^j). The S_{ij} with $i \neq j$ are the transmission coefficients, and the S_{jj} are the reflection coefficients.

For this comparison of the computed coefficients with the measured ones, the imaging chamber is filled with a homogenous matching solution. The electric permittivity ε of the matching solution is chosen by EMTensor in order to minimize contrasts with the ceramic-loaded waveguides and with the different brain tissues. The choice of the conductivity σ of the matching solution is a compromise between the minimization of reflection artifacts from metallic boundaries and the desire to have best possible signal-to-noise ratio. Here the relative complex permittivity of the matching solution at frequency $f = 1 \text{ GHz}$ is $\varepsilon_r^{\text{gel}} = 44 - 20i$. The relative complex permittivity inside the ceramic-loaded waveguides is $\varepsilon_r^{\text{cer}} = 59 - 0i$. Here with ε_r we mean the ratio between the complex permittivity ε_σ and the permittivity of free space ε_0 .

For this test case, the set of experimental data given by EMTensor consists in transmission coefficients for transmitting antennas in the second ring from the top. Figure 3 shows the normalized magnitude (dB) and phase (degree) of the complex coefficients S_{ij} corresponding to a transmitting antenna in the second ring from the top and to the 31 receiving antennas in the middle ring (notice that measured coefficients are available only for 17 receiving antennas). The magnitude in dB is calculated as $20 \log_{10}(|S_{ij}|)$. The computed coefficients are obtained by solving the direct problem with edge finite elements of polynomial degree $r = 2$. We can see that the computed transmission coefficients are in very good agreement with the measurements.

5.2 Efficiency of high order finite elements

The goal of the following numerical experiments is to assess the efficiency of the high order finite elements described in Section 3 compared to the classical lowest order edge elements in terms of accuracy and computing time, which are of great importance for such an application in brain imaging. For this test case, a non-dissipative plastic-filled cylinder of diameter 6 cm and relative permittivity $\varepsilon_r^{\text{cy1}} = 3$ is inserted in the imaging chamber and surrounded by matching solution of relative complex permittivity $\varepsilon_r^{\text{gel}} = 44 - 20i$ (see Figure 4). We consider

Figure 3: The normalized magnitude (top) and phase (bottom) of the transmission coefficients computed with the simulation and measured experimentally.

the 32 antennas of the second ring from the top as transmitting antennas at frequency $f = 1$ GHz, and all 160 antennas are receiving. We evaluate the relative error on the reflection and transmission coefficients S_{ij} with respect to the coefficients S_{ij}^{ref} computed from a reference solution. The relative error is calculated with the following formula:

$$E = \frac{\sqrt{\sum_{j,i} |S_{ij} - S_{ij}^{\text{ref}}|^2}}{\sqrt{\sum_{j,i} |S_{ij}^{\text{ref}}|^2}}. \quad (7)$$

The reference solution is computed on a fine mesh of approximately 18 million tetrahedra, which corresponds to 20 points per wavelength, and using edge finite elements of degree $r = 2$, resulting in 114 million unknowns. Slices in Figures 4 and 5 show the computational domain and the solution \mathbf{E}^j for one transmitting antenna j in the second ring from the top.

We compare the computing time and the relative error (7) for different numbers of unknowns corresponding to several mesh sizes, for approximation degrees $r = 1$ and $r = 2$. All these simulations are done using 512 subdomains with one MPI process and two OpenMP threads per subdomain, for a total of 1024 cores on the Curie supercomputer.

We report the results in Table 1 and in Figure 6. As we can see, the high order approximation ($r = 2$) allows to attain a given accuracy with much fewer unknowns and much

less computing time than the lowest order approximation ($r = 1$). For example, at a given accuracy of $E \approx 0.1$, the finite element discretization of degree $r = 1$ requires 21 million unknowns and a computing time of 130 seconds, while the high order finite element discretization ($r = 2$) only needs 5 million unknowns, with a corresponding computing time of 62 seconds.

6 Conclusion

This work shows the benefits of using a discretization of the time-harmonic Maxwell's equations based on high order edge finite elements coupled with a parallel domain decomposition preconditioner for the simulation of a microwave imaging system. In such complex systems, accuracy and computing speed are of paramount importance, especially for the application considered here of brain stroke monitoring.

Ongoing work consists in incorporating high order methods in the inversion tool that we are developing in the context of this application in brain imaging, for which promising results have already been obtained with edge finite elements of lowest order for the reconstruction from synthetic data of a numerical brain model.

We are also now in a position to test our inversion algorithm on various data sets acquired

by the measurement system prototype of EMTensor.

From the numerical point of view, promising techniques are available that will allow us to speed up the solution of the inverse problem. First, recycling and block methods can be very helpful in such a context. The inverse problem is solved by a local optimization algorithm which consists in solving a sequence of slowly-varying linear systems, and a recycling algorithm such as GCRO-DR (Generalized Conjugate Residual method with inner Orthogonalization and Deflated Restarting) [14] can significantly reduce the total number of iterations over all linear systems, by recycling the Krylov subspace from one linear system solve to the next. Moreover, each iteration in the inversion loop corresponds to solving a linear system with multiple right-hand sides available simultaneously, with one right-hand side per transmitting antenna. Each direct problem with multiple right-hand sides can thus be solved efficiently by block methods such as Block GMRES, or by combining block and recycling strategies in a Block GCRO-DR algorithm. Block methods provide higher arithmetic intensity and better convergence.

Finally, choosing a suitable coarse space for the design of a scalable two-level preconditioner for Maxwell's equations is still an open problem. Indeed, enriching the one-level preconditioner presented here with an efficient two-level preconditioner would lead to better convergence when using many subdomains, resulting in a highly scalable parallel solver.
